Counterpoint: Long-Term Antibiotic Therapy Improves Persistent Symptoms Associated with Lyme Disease

Raphael B. Stricker
International Lyme and Associated Diseases Society, Bethesda, Maryland

(See the point by Auwaerter on pages 143–8)

Background. Controversy exists regarding the diagnosis and treatment of Lyme disease. Patients with persistent symptoms after standard (2–4-week) antibiotic therapy for this tickborne illness have been denied further antibiotic treatment as a result of the perception that long-term infection with the Lyme spirochete, *Borrelia burgdorferi*, and associated tickborne pathogens is rare or nonexistent.

Methods. I review the pathophysiology of *B. burgdorferi* infection and the peer-reviewed literature on diagnostic Lyme disease testing, standard treatment results, and coinfection with tickborne agents, such as *Babesia*, *Anaplasm*, *Ehrlichia*, and *Bartonella* species. I also examine uncontrolled and controlled trials of prolonged antibiotic therapy in patients with persistent symptoms of Lyme disease.

Results. The complex “stealth” pathology of *B. burgdorferi* allows the spirochete to invade diverse tissues, elude the immune response, and establish long-term infection. Commercial testing for Lyme disease is highly specific but relatively insensitive, especially during the later stages of disease. Numerous studies have documented the failure of standard antibiotic therapy in patients with Lyme disease. Previous uncontrolled trials and recent placebo-controlled trials suggest that prolonged antibiotic therapy (duration, >4 weeks) may be beneficial for patients with persistent Lyme disease symptoms. Tickborne coinfections may increase the severity and duration of infection with *B. burgdorferi*.

Conclusions. Prolonged antibiotic therapy may be useful and justifiable in patients with persistent symptoms of Lyme disease and coinfection with tickborne agents.

Lyme disease is a controversial illness [1–6]. The classic features of the disease include receipt of a tick bite followed by the so-called erythema migrans or “bullseye” rash and significant joint swelling typical of arthritis. Unfortunately, the classic features of this tickborne disease are not always present. For example, only 50%–60% of patients with Lyme disease recall having received a tick bite, and often the erythema migrans rash is absent or not in the shape of a bullseye [5, 6]. According to health departments around the United States, the typical bullseye rash is only reported in 35%–60% of patients with Lyme disease [7, 8]. Furthermore, frank arthritis is only seen in 20%–30% of patients with Lyme disease [1, 2]. Thus, the classic features of the disease may be absent, and the diagnosis may be easily missed [1–4].

In the absence of typical features of Lyme disease, patients may go on to develop a syndrome with multiple nonspecific symptoms that affect various organ systems, including the joints, muscles, nerves, brain, and heart. The myriad symptoms prompt the question whether this is “post–Lyme disease syndrome,” a poorly defined entity triggered by Lyme disease, or whether these symptoms are caused by persistent infection with the Lyme spirochete, *Borrelia burgdorferi*. To address this question, we must first examine the pathophysiology of the disease.

PATHOPHYSIOLOGY OF LYME DISEASE

*B. burgdorferi* is a fascinating bacterium [9, 10]. It has >1500 gene sequences with at least 132 functioning
Growing evidence of an emerging tick-borne disease that causes a Lyme like illness for many Australian patients

response [11–13]. The spirochete to penetrate the skin and evade the local immune

munosuppressive factors is expressed into the wound, allowing

rochete, tick saliva containing analgesic, anticoagulant, and im-

During a tick bite and before transmission of the Lyme spi-

PHYSICAL SECLUSION

The Lyme spirochete uses physical seclusion at intracellular sites

as a means of evading the immune response in multiple cell
types, including synovial cells, endothelial cells, fibroblasts,
macrophages, Kupffer cells, and neuronal cells [34–43]. In cul-
ture, B. burgdorferi can be grown in fibroblasts for >8 weeks, suggesting that the organism can thrive over long periods of
time in the right place and under the right conditions.

Physical seclusion at extracellular sites, including the joints,
eyes, and CNS, may also promote survival of the Lyme spi-

rochete. In addition, B. burgdorferi engages in “cloaking” me-

chанизms by binding to proteoglycan, collagen, plasminogen, in-
tegrin, and fibronectin. These substances can mask the

bacterium and make it invisible to the immune system

[38–42].

SECRETED FACTORS

There are a number of factors that are secreted either by B.

burgdorferi itself or in response to infection with the spirochete

[44–51]. For a number of years, it has been known that B.

burgdorferi secretes a hemolysin, although its function is un-
certain [44]. More recently, the spirochete has been shown to

elaborate porin and adhesin, 2 proteins that allow bacteria to

adhere to cells and pierce the cell wall to gain entry [45].

Even more recently, B. burgdorferi was found to secrete pher-

omones, including AI-2, which is also secreted by mycobacteria

[46–50]. This is the first time that a spirochete has been shown to

secrete an autoinducer and suggests that the Lyme spirochete

engages in autoresuscitation like other dormant organisms,
such as the tubercle bacillus [46–50]. In addition, B. burgdorferi

can induce secretion of aggregacase, an enzyme that damages
cartilage [51]. This may be a mechanism by which the bacte-
rium induces damage and inflammation in joints. Armed with

these weapons of “stealth pathology,” the Lyme spirochete is a

formidable infectious agent.

LABORATORY TESTING

Let’s turn briefly to laboratory testing in Lyme disease. A major

problem is that current commercial Lyme serologic tests are

not sensitive enough for diagnosis, especially during the later

stages of disease [52–64]. The Centers for Disease Control and

Prevention (CDC) advocates a “2-tier” testing system using an

ELISA or immunofluorescence assay as a screening test, fol-

lowed by a Western blot for confirmation if the result of the

ELISA or immunofluorescence assay is positive. The CDC cau-
tions, however, that the 2-tier system should only be used for

surveillance purposes and not for diagnosis, and the reason for

this warning is clear: although the 2-tier system has a very high

specificity (99%–100%), thus avoiding the false-positive results

that are the bane of surveillance statistics, it has relatively poor

IMMUNOSUPPRESSION

During a tick bite and before transmission of the Lyme spi-

rochete, tick saliva containing analgesic, anticoagulant, and im-

munosuppressive factors is expressed into the wound, allowing

the spirochete to penetrate the skin and evade the local immune

response [11–50]. Stealth pathology involves 4 basic

strategies: immunosuppression; genetic, phase, and antigenic

variation; physical seclusion; and secreted factors (table 1).

These strategies are outlined below.

GENETIC, PHASE, AND ANTIGENIC VARIATION

B. burgdorferi engages in genetic, phase, and antigenic variation

that shares various features with other organisms [20–23]. For
general, gene switching is similar to what is seen with try-

panosomes, mutation and recombination are typical of HIV,

variable antigen expression is seen with Neisseria species, au-
toinduction of dormant organisms occurs in mycobacterial in-
fection, and fibronectin binding occurs with staphylococcal and

streptococcal infection.

B. burgdorferi may assume a dormant state with cyst for-
mation [24–29]. Although spirochetal persistence in the cyst
form is a controversial issue, it has recently been shown that

neutrophil calprotectin can induce a dormant state in the spi-

rochete, allowing it to persist in tissue without replicating and

providing the means to avoid antibiotics [30].

Although antibiotic resistance associated with gene mutation

was previously thought to be rare in B. burgdorferi infection
[31], recent studies have demonstrated gene mutations in the

Lyme spirochete that confer in vitro resistance to various an-
tibiotics [32, 33]. The clinical implication of these gene mu-
tations is uncertain at present.

genes. In contrast, Treponema pallidum, the spirochetal agent

of syphilis, has only 22 functioning genes. The genetic makeup

of B. burgdorferi is quite unusual. It has a linear chromosome

and 21 plasmids, which are extrachromosomal strands of DNA.

This is 3 times more plasmids than any other known bacteria

(Chlamydia comes in a distant second, with 7 plasmids). Plas-
mids are thought to give bacteria a kind of “rapid response” sys-

tem that allows them to adapt very rapidly to changes in

the environment, and the complex genetic structure of B. burg-
dorferi suggests that this is a highly adaptable organism [9, 10].

In addition to its complex genetic makeup, B. burgdorferi

engages in so-called “stealth pathology” to evade the human

immune response [11–50]. Stealth pathology involves 4 basic

strategies: immunosuppression; genetic, phase, and antigenic

variation; physical seclusion; and secreted factors (table 1).

These strategies are outlined below.
Growing evidence of an emerging tick-borne disease that causes a Lyme-like illness for many Australian patients.

TREATMENT OF LYME DISEASE

We can start with animal models of Lyme disease [67–75]. In the mouse, one study found that “persistance of spirochtes within macrophages provides a possible pathogenetic mechanism for chronic or recurring Lyme disease” [67, p. 909]. In another study, “nine months after treatment, low levels of spirochete DNA could be detected by real time PCR in a subset of antibiotic treated mice” [68, p. 1430]. So at least in the mouse model, spirochetes may persist after appropriate treatment.

Next is the dog model—a particularly convincing model, because Straubinger et al. [69] revealed that, in dogs that had been experimentally infected with B. burgdorferi by tick exposure, treatment with high doses of amoxicillin or doxycycline for 30 days diminished persistent infection but failed to eliminate it. Furthermore, when dogs were observed for a 500-day postinfection period (the equivalent of 3–4 human years), B. burgdorferi DNA was detectable at low levels in multiple tissue samples obtained from the dogs, despite the administration of “adequate” antibiotic treatment [70].

Finally, in a model using our closest relative, the nonhuman primate macaque monkey, Pachner and colleagues [71–75] found that neurologic and cardiac disease were associated with persistent infection in these monkeys, and cytokine and gene expression related to persistent B. burgdorferi infection could be demonstrated >3 months after infection. In summary, these animal models provide “credible scientific evidence” for persistent infection in Lyme disease.

HUMAN STUDIES

Turning to human studies, there are a number of reports that show persistent symptoms of Lyme disease after short-term antibiotic therapy [76–96]. Persistent symptoms have been noted in 25%–80% of patients with Lyme disease after 2–4 weeks of antibiotic therapy [76–87]. Furthermore, infection that was determined to be persistent on the basis of either culture or PCR evidence has been documented in up to 40% of patients following receipt of the “adequate” antibiotic treatment recommended by the IDSA [88–96]. For example, positive culture and PCR results were found in synovium and synovial fluid specimens obtained from a patient 7 years after treatment [92], and a positive result was reported for a culture of an iris biopsy specimen obtained from a treated patient [93]. These reports suggest that short-term antibiotic therapy may suppress the Lyme spirochete but not eradicate it.

In another case, the patient’s condition deteriorated despite receipt of repeated courses of antibiotic treatment over a 2-

NOTE. IV Ctri, intravenous ceftriaxone; SI, significant improvement.
year period. She received 12 months of intravenous antibiotic treatment, followed by 11 months of oral antibiotics, and her condition improved significantly [95]. Thus, this case report suggests that longer treatment may be beneficial in some patients with Lyme disease. Taken as a whole, these studies provide “credible scientific evidence” for persistence of B. burgdorferi infection after “adequate” short-term antibiotic treatment in humans.

That brings up the next question: does longer antibiotic treatment help in persistent Lyme disease? There have been a number of uncontrolled trials that support longer treatment of persistent disease symptoms [97–100]. The largest study included 277 patients who were treated with tetracycline for 1–11 months (mean duration, 4 months). The study showed that, after 2 months of therapy, 33% of patients had improvement in symptoms, but after 3 months of treatment, 61% of patients had decreased symptoms [97]. So this study suggests that longer treatment may result in better symptom outcome in Lyme disease. There have been other small, uncontrolled trials showing that longer treatment may have better symptom outcomes in patients with Lyme disease, including one trial that showed that patients who were re-treated with intravenous therapy had the greatest improvement in their symptoms [98–100].

In contrast to these uncontrolled trials, 2 randomized, placebo-controlled trials examined re-treatment of patients with persistent symptoms of Lyme disease (table 2) [101, 102]. Krupp et al. [102] studied 1 month of intravenous ceftriaxone, whereas Klempner et al. [101] studied 1 month of intravenous ceftriaxone followed by 2 months of oral doxycycline. The Krupp study showed improvement in fatigue with its 30-day treatment regimen, whereas the Klempner study showed no improvement in quality of life following re-treatment for 90 days. The main problem with these studies is that they included patients who had been symptomatic for an average of 4–5 years, and treatment with 1 month of intravenous antibiotics, with or without low-dose doxycycline, is insufficient for patients who have been sick this long [103, 104]. Thus, the generalizability of results in these highly selected patients with persistent Lyme disease is questionable [104].

In contrast to these studies, 2 placebo-controlled trials were presented in 2005 at the Columbia/Lyme Disease Association’s annual meeting (table 2) [105, 106]. One study involved oral amoxicillin for 3 months versus placebo for previously treated patients, and re-treatment was successful for the two-thirds of patients with the best initial quality of life. A second study administered intravenous ceftriaxone for 10 weeks to patients with persistent neurologic symptoms of Lyme disease, and these patients had significant cognitive improvement with this treatment. We look forward to publication of these 2 placebo-controlled trials, which show that longer courses of antibiotic therapy are useful in patients with persistent Lyme disease.

### COINFECTION WITH TICKBORNE AGENTS

In addition to infection with B. burgdorferi, tick-borne coinfections are being recognized more frequently. If a patient is treated for Lyme disease and has symptoms that have persisted or worsened, the lack of improvement may be due to the presence of Babesia, Anaplasma, Ehrlichia, or Bartonella coinfection [107–126]. Coinfection with Babesia and Ehrlichia has been shown to exacerbate Lyme disease in mouse models [108–110] and also in humans [111–118]. Traditionally, Babesia, Anaplasm, Ehrlichia and Bartonella are thought to produce acute fulminant infections, but in fact these pathogens may cause low-grade infections that can increase the severity and duration of Lyme disease [119–125].

A disturbing study from New Jersey examined the prevalence of coinfections in Ixodes ticks that transmit Lyme disease [126]. In that study, the prevalence of B. burgdorferi infection was 33.6%, but the prevalence of Bartonella infection was 34.5%. Thus, Bartonella species were found more often than the Lyme spirochete in these ticks. This observation presages a greater problem with Bartonella infection associated with tick exposure in the near future.

### TREATMENT APPROACH TO CHRONIC LYME DISEASE

What is the approach for a patient who presents with persistent symptoms of Lyme disease [127–140]? First, the Lyme Western blot should be repeated, and coinfection testing should be performed by a laboratory that is proficient in tick-borne disease analysis. At the same time, other medical problems that could

**NOTE.** Data are based on [143–147].
cause persistent symptoms should be ruled out. Measurement of the CD57 natural killer cell level, which is an immunologic marker that can be used to monitor treatment in chronic Lyme disease, should be performed [129–131]. If neurologic symptoms are severe, a single-photon emission CT SPECT brain scan should be obtained, to see how much inflammation is present in the brain. Neuropsychiatric evaluation may also be helpful [132].

On the basis of these results, coinfections should be treated first, if any are present, and then oral or parenteral antibiotics should be used to treat symptoms of persistent Lyme disease. Antibiotic therapy should be administered in a rotating and open-ended manner, in conjunction with probiotics, to minimize adverse effects [133–136]. Monitoring of clinical symptoms, CD57 natural killer cell levels, and markers of inflammation should be performed in conjunction with treatment [137–140].

This approach differs from the recommendations of the current IDSA guidelines, which do not recognize persistent infection in chronic Lyme disease [141]. However, the treatment approach is consistent with the guidelines of the International Lyme and Associated Diseases Society, which mandates treatment for persistent infection in patients with chronic Lyme disease symptoms [142]. It is helpful to recall that B. burgdorferi shares certain pathophysiological features with mycobacterial infection and other chronic infections (table 1), that these infections may require prolonged antibiotic therapy (6–36 months), and that the risks of long-term treatment are considered justifiable in those situations (table 3) [143–147]. On the basis of the foregoing discussion, prolonged antibiotic therapy appears to be useful and justifiable in chronic Lyme disease.

In summary, >18,000 scientific articles have been written about Lyme disease. Some of these articles focus on the complex pathophysiology of B. burgdorferi, whereas others highlight the clinical uncertainty surrounding tickborne disease. Because the optimal therapy for this complicated illness is still in doubt, we must keep an open mind about the treatment of patients who present with persistent symptoms of Lyme and associated tickborne diseases.
